F.1 INVENTORIES

F.1.1 Current Wetland Area and Rates of Loss

The ability to estimate soil carbon pools and fluxes in North American wetlands is constrained by the national inventories (or lack thereof) for Canada, the United States, and Mexico (Davidson *et al.*, 1999). The National Wetland Inventory (NWI) program of the United States has repeatedly sampled several thousand wetland sites using aerial photographs and more limited field verification. The data are summarized in a series of reports detailing changes in wetland area in the conterminous United States for the periods of the mid-1950s to mid-1970s (Frayer *et al.*, 1983), mid-1970s to mid-1980s (Dahl and Johnson, 1991), and 1986 to 1997 (Dahl, 2000). We used these relatively high-quality data sets extensively for estimating wetland area and loss rates in the conterminous United States, including mud flats. However, the usefulness of the NWI inventory reports for carbon budgeting is limited by the level of classification used to define wetland categories within the Cowardin *et al.* (1979) wetland classification system. At the level used in the national status and trend reports, vegetated freshwater wetlands are classified by dominant physiognomic vegetation type, and it is impossible to make the important distinction between wetlands with deep organic soils (*i.e.*, peatlands) and wetlands with mineral soils. The data are not at an adequate spatial resolution to combine with U.S. Department of Agriculture (USDA) Natural Resources Conservation Service (NRCS) soil maps to discriminate between the two types of wetlands (T. Dahl, personal comm.). Because of these data limitations, we used the NRCS soil inventory of peatlands (*i.e.*, Histosols and Histels, or peatlands with and without permafrost, respectively) to estimate original peatland area (Bridgham *et al.*, 2000) and combined these data with regional estimates of loss (Armentano and Menges, 1986) to estimate current peatland area in the conterminous United States. We calculated the current area of freshwater mineral-soil (FWMS) wetlands in the conterminous United

States by subtracting peatland area from total wetland area (Dahl, 2000). This approach was limited by the Armentano and Menges peatland area data being current only up to the early 1980s, although large losses of peatlands since then are unlikely due to the institution of wetland protection laws.

We used a similar approach for Alaskan peatlands: peatland area was determined by the NRCS soil inventory (N. Bliss, query of the NRCS State Soil Geographic [STATSGO] database, February 2006) and overall wetland inventory was determined by standard NWI methods (Hall *et al.*, 1994). However, our peatland estimate of 132,000 km² (Table F.1) is 22% of the often cited value by Kivinen and Pakarinen (1981) of 596,000 km².

Kivinen and Pakarinen also used NRCS soils data (Rieger *et al.*, 1979) for their peatland estimates, but they defined a peatland as having a minimum organic layer thickness of 30 cm, whereas the current United States and Canadian soil taxonomies require a 40-cm thickness. The original 1979 Alaska soil inventory has been reclassified with current United States soil taxonomy (J. Moore, Alaska State Soil Scientist, personal comm.). Using the reclassified soil inventory, Alaska has 417,000 km² of wetlands with a histic modifier (*i.e.*, a surface organic layer between 20 and 60 cm thick) that are not Histosols or Histels, indicating significant carbon accumulation in the surface horizons of FWMS wetlands. Thus, we conclude that Kivinen and Pakarinen's Alaska peatland area estimate is higher because many Alaskan wetlands have a thin organic horizon that is not deep enough to qualify as a peatland under current soil taxonomy. Our smaller peatland area significantly lowers our estimate of carbon pools and fluxes in Alaskan peatlands compared to earlier studies (see *Carbon Pools* below).

The area of salt marsh in the conterminous United States, Canada, and Alaska were taken from Mendels-

Table F.1 Current and historical area of wetlands in North America and the world ($\times 10^3$ km²). Historical refers to approximately 1800, unless otherwise specified.

^q ND indicates that no data are available.

^r Assuming that historical proportion of peatlands to total wetlands in Mexico was the same as today.

^s Bridgman *et al.* (2000) for the United States, Tarnocai *et al.* (2005) for Canada, Joosten, and Clarke (2002) for the rest of world.

Recent range in literature 2,974,000–3,985,000 km² (Matthews and Fung, 1987; Aselmann and Crutzen, 1989; Maltby and Immirzi, 1993; Bridgman *et al.*, 2000; Joosten and Clarke, 2002).

^t Average of 2,289,000 km² from Matthews and Fung (1987) and 2,341,000 km² Aselmann and Crutzen (1989).

^u Chmura *et al.* (2003). Underestimated because no inventories were available for the continents Asia, South America, and Australia which are mangrove-dominated but also support salt marsh.

^v Spalding (1997).

^w Range from 3,880 to 4,086 in Maltby and Immirzi (1993).

^x Approximately 50% loss from Moser *et al.* (1996).

^y Assumed a 25% loss rate outside North America for tidal marshes; a loss rate of 35% was used for mangroves (Valiela *et al.*, 2001).

sohn and McKee (2000). Because these estimates include brackish tidal marshes, they cannot be compared directly to the area of Canadian salt marshes. Compilations of freshwater, tidal wetland area are difficult to find, but there is approximately 1,640 km² on the east coast of the United States (Odum *et al.*, 1984) and 470 km² on the United States' Gulf Coast (Field *et al.*, 1991). Although some freshwater tidal wetlands are forested, this total was added to the tidal marsh area for the conterminous United States. Mangrove area was taken from Mendelsohn and McKee (2000), and is similar to an estimate by Lugo and Snedaker (1974).

The original area of tidal wetlands in the conterminous United States was based on the NWI (Dahl, 2000), which we considered to be the most defensible estimate available. However, "original" here only refers to the 1950s, when the first national wetland inventory was conducted in the conterminous United States to provide a historic baseline area. It is almost certain that the actual loss of tidal wetland area in the conterminous United States over a longer time frame was larger than the 7.7% figure used in our calculation. Valiela *et al.* (2001) estimated a loss of 31% of mangrove area in the United States from 1958 to 1982, but acknowledged a high level of uncertainty in this figure. We assumed that the original area of Alaskan tidal wetlands was similar to the current area because there has been relatively little development pressure in Alaska. To estimate loss of global tidal wetlands, we arbitrarily used a figure of 35% loss for tidal marshes outside of the United States and Mexico.

A regular national inventory of Canada's wetlands has not been undertaken, although wetland area has been mapped by ecoregion (National Wetlands Working Group, 1988). Extensive recent effort has gone into mapping Canadian peatlands (Tarnocai, 1998; Tarnocai *et al.*, 2005). We calculated the current area of mineral-soil wetlands as the difference between total wetland area and peatland area in National Wetland Working Group (1988). The original area of FWMS wetland area was obtained from Rubec (1996). Canadian salt marsh estimates were taken from a compilation by Mendelsohn and McKee (2000). The compilation does not include brackish or freshwater tidal marshes, and we were unable to locate other estimates of Canadian brackish marsh area. The original area of salt marshes was estimated from the National Wetland Working Group (1988), but it is highly uncertain. There are no reliable country-wide estimates of mud flat area for Canada, but a highly uncertain extrapolation from a limited number of regional estimates was possible based upon the ratio of mudflat to salt marsh area reported by Hanson and Calkins (1996).

No national wetland inventories have been done for Mexico. Current freshwater wetland estimates for Mexico were taken from Davidson *et al.* (1999) and Spiers (1999), who

used inventories of discrete wetland regions performed by a variety of organizations. Thus, freshwater wetland area estimates for Mexico are highly unreliable and are possibly a large underestimate. For mangrove area in Mexico, we used the estimates compiled by Mendelsohn and McKee (2000), which are similar to estimates reported in Davidson *et al.* (1999) and Spalding *et al.* (1997). We could find no estimates of tidal marsh or mud flat area for Mexico. Since most vegetated Mexican tidal wetlands are dominated by mangroves (Olmsted, 1993; Mendelsohn and McKee, 2000), the omission of Mexican tidal marshes should not significantly affect our carbon budget. However, there may be large areas of mud flat that would significantly increase our estimate of carbon pools and sequestration in this country. We used the Valiela *et al.* (2001) estimate of 38% for mangrove loss in the Americas, which roughly covers the period 1980 to 1990. This is less than the rough worldwide estimate of 50% wetland loss since the 1880s that is often cited (see Zedler and Kercher, 2005) and is probably conservative. A global loss rate of 35% was used for mangrove area globally based on the analysis of Valiela *et al.* (2001).

F.2 CARBON POOLS

F.2.1 Freshwater Mineral-Soil (Gleysol) Carbon Pools

Gleysol is a soil classification used by the Food and Agriculture Organization (FAO) and many countries that denotes mineral soils formed under waterlogged conditions (FAO-UNESCO, 1974). Tarnocai (1998) reported a soil carbon density of 200 Mg C per hectare (ha) for Canadian Gleysols to 1-m depth. Batjes (1996) determined soil carbon content globally from the Soil Map of the World (FAO, 1991) and a large database of soil pedons. He estimated an average value for soil carbon density of 199 Mg C per ha (CV¹ = 212%, n = 14 pedons) for Gleysols of the world to 2-m depth; to 1-m depth, he reported a soil carbon density of 131 Mg C per ha (CV = 109%, n = 142 pedons).

Gleysols are not part of the United States' soil taxonomy scheme, and mineral soils with attributes reflecting waterlogged conditions are distributed among numerous soil groups. We queried the NRCS State Soil Geographic (STATSGO) soils database for soil carbon density in "wet" mineral soils of the conterminous United States (all soils that had a surface texture described as peat, muck, or mucky peat, or appeared on the 1993 list of hydric soils, which were not classified as Histosols) (N. Bliss, query of NRCS STATSGO database, December 2005). We used the average soil carbon densities of 162 Mg C per ha from this query for FWMS wetlands in the conterminous United States and Mexico.

¹ CV is the "coefficient of variation," or 100 times the standard deviation divided by the mean.

Table F.2 Soil carbon pools (Gt) and fluxes (Mt per year) of wetlands in North America and the world. “Sequestration in current wetlands” refers to carbon sequestration in extant wetlands; “oxidation in former wetlands” refers to emissions from wetlands that have been converted to non-wetland uses or conversion among wetland types due to human influence; “historical loss in sequestration capacity” refers to the loss in the carbon sequestration function of wetlands that have been converted to non-wetland uses; “change in flux from wetland conversions” is the sum of the two previous fluxes. Positive flux numbers indicate a net flux into the atmosphere, whereas negative numbers indicate a net flux into the ecosystem.

^aTarnocai (1998); mineral soil to 1-m depth.

^bTarnocai *et al.* (2005).

^cRates and pools calculated from Chmura *et al.* (2003) using country-specific data (sedimentation accumulation rates in Mg C per ha per year: Mexican mangroves = 3.3, conterminous United States mangroves = 1.8, conterminous United States tidal marshes = 2.2, tidal marshes in Canada and Alaska = 2.1); areas from Table 13F.1.

^dAssumed the same carbon density and accumulation rates as the adjacent vegetated wetland ecosystem (mangrove data for Mexico and salt marsh data elsewhere).

^eAssumed carbon accumulation rate of 0.13 Mg C per ha per year for permafrost peatlands and 0.19 Mg C per ha per year for non-permafrost peatlands. Reported range of long-term apparent accumulation rates from 0.05-0.35 (Ovenden, 1990; Maltby and Immerzi, 1993; Trumbore and Harden, 1997; Vitt *et al.*, 2000; Turunen *et al.*, 2004).

^fRate calculated as the geometric mean sediment accumulation rate of 2.2 Mg sediment per ha per year (range 0-80) from Johnston (1991) and Craft and Casey (2000) times 7.7 % C (CV = 109) (Batjes 1996).

^gSum of 0.24 Mt C per year from horticulture removal of peat (Cleary *et al.*, 2005) and 0.10 Mt C per year from increased peat sequestration due to permafrost melting (Turetsky *et al.*, 2002).

^hAssumed that the net oxidation of 8.6% of the soil carbon pool (Euliss *et al.*, 2006) over 50 years after conversion to non-wetland use.

ⁱAssumed that conversion of tidal systems is caused by fill and results in burial and preservation of SOM, Sedimentary Organic Matter, rather than oxidation.

^jSoil carbon densities of 1,441 Mg C per ha for Histosols and 1,048 Mg C per ha for Histels (Tarnocai *et al.*, 2005).

^kSoil carbon density of 162 Mg C per ha for the conterminous United States and Mexico and 468 Mg C per ha for Alaska based upon NRCS STATSGO database and soil pedon information.

^lAssumed soil carbon density of 1,500 Mg C per ha.

^mWebb and Webb (1988).

ⁿEstimated loss rate as of early 1980s (Armentano and Menges, 1986). Overall, wetlands losses in the United States have declined dramatically since then (Dahl, 2000) and probably even more so for Histosols, so this number may still be representative.

^oUsing peat accumulation rate of 1.6 Mg C per ha (range 1.0–2.25) (Maltby and Immerzi, 1993).

^pFrom Maltby and Immerzi (1993). Range of 234 to 679 GtC (Gorham, 1991; Maltby and Immerzi, 1993; Eswaran *et al.*, 1995; Batjes, 1996; Lappalainen, 1996; Joosten and Clarke, 2002).

^qSoil carbon density of 199 Mg C per ha (Batjes, 1996).

^rChmura *et al.* (2003).

^sJoosten and Clarke (2002) reported range of -40 to -70 Mt C per year. Using the peatland estimate in Table F.1 and a C accumulation rate of 0.19 Mg C per ha per year, we calculate a global flux of -65 Mt C per year in peatlands.

^tCurrent oxidative flux is the difference between the change in flux and the historical loss in sequestration capacity from this table. The change in flux is from Maltby and Immerzi (1993) (reported range 176 to 266 Mt C per year) and the historical loss in sequestration capacity is from this table for North America, from Armentano and Menges (1986) for other northern peatlands, and from Maltby and Immerzi (1993) for tropical peatlands.

^uAssumed that global rates approximate the North America rate because most salt marshes inventoried are in North America.

^vAssumed 25% loss globally since the late 1800s.

ND indicates that no data are available.

Some caution is necessary regarding the use of Gleysol or “wet” mineral soil carbon densities because apparently they include large areas of seasonally wet soils that are not considered wetlands by the more conservative definition of wetlands used by the United States and many other countries and organizations. For example, Eswaran *et al.* (1995) estimated that global wet mineral-soil area was 8,808,000 km², which is substantially higher than the commonly accepted mineral-soil wetland area estimated by Matthews and Fung (1987) of 2,289,000 km² and Aselmann and Crutzen (1989) of 2,341,000 km², even accounting for substantial global wetland loss. In our query of the NRCS STATSGO database for the United States, we found 1,258,000 km² of wet soils in the conterminous United States versus our estimate of 312,000 km² of FWMS wetlands, currently,

and 762,000 km², historically (Table F.1). We assume that including these wet-but-not-wetland soils will decrease the estimated soil carbon density, but to what degree we do not know. However, just considering the differences in area will give large differences in the soil carbon pool. For example, Eswaran *et al.* (1995) estimated that wet mineral soils globally contain 108 Gt C to 1-m depth, whereas our estimate is 46 Gt C to 2-m depth (Table F.2).

For Alaska, many soil investigations have been conducted since the STATSGO soil data was coded. We updated STATSGO by calculating soil carbon densities from data obtained from the NRCS on 479 pedons collected in Alaska, and then we used this data for both FWMS wetlands and peatlands. For some of the Histosols, missing bulk densities

were calculated using averages of measured bulk densities for the closest matching class in the USDA Soil Taxonomy (NRCS, 1999). A matching procedure was developed for relating sets of pedons to sets of STATSGO components. If there were multiple components for each map unit in STATSGO, the percentage of the component was used to scale area and carbon data. We compared matching sets of pedons to sets of components at the four top levels of the United States' soil taxonomy: Orders, Suborders, Great Groups, and Subgroups. For example, the soil carbon for all pedons having the same soil order were averaged, and the carbon content was applied to all of the soil components of the same order (*e.g.*, Histosol pedons are used to characterize Histosol components). At the Order level, all components were matched with pedon data. At the suborder level, pedon data were not available to match approximately 20,000 km² (compared to the nearly 1,500,000-km² area of soil in the state), but the soil characteristics were more closely associated with the appropriate land areas than at the Order level. At the Great Group and Subgroup levels, pedon data were unavailable for much larger areas, even though the quality of the data when available became better. For this study, we used the Suborder-level matching. The resulting soil carbon density for Alaskan FWMS wetlands was 469 Mg C per ha, reflecting large areas of wetlands with a histic epipedon as noted above.

F.2.2 Peatland Soil Carbon Pools

The carbon pool of permafrost and non-permafrost peatlands in Canada had been previously estimated by Tarnocai *et al.* (2005) based upon an extensive database. Good soil-carbon density data are unavailable for peatlands in the United States, as the NRCS soil pedon information typically only goes to a maximum depth of between 1.5 to 2 m, and many peatlands are deeper than this. Therefore, we used the carbon density estimates of Tarnocai *et al.* (2005) of 1,441 Mg C per ha for Histosols and 1,048 Mg C per ha for Histels to estimate the soil carbon pool in Alaskan peatlands.

The importance of our using a smaller area of Alaskan peatlands becomes obvious here. Using the larger area from Kivinen and Pakarinen (1981), Halsey *et al.* (2000) estimated that Alaskan peatlands have a soil carbon pool of 71.5 Gt, almost 5-fold higher than our estimate. However, some of the difference in soil carbon between the two estimates can be accounted for by the 26 Gt C that we calculated resides in Alaskan FWMS wetlands (Table F.2).

The peatlands of the conterminous United States are different in texture, and probably depth, from those in Canada and Alaska, so it is probably inappropriate to use the soil carbon densities for Canadian peatlands for those in the conterminous United States. For example, we compared the relative percentage of the Histosol suborders (excluding the

small area of Folists, as they are predominantly upland soils) for Canada (Tarnocai, 1998), Alaska (updated STATSGO data, J. Moore, personal comm.), and the conterminous United States (NRCS, 1999). The relative percentage of Fibrists, Hemists, and Saprists, respectively, in Canada are 37%, 62%, and 1%, in Alaska are 53%, 27%, and 20%, and in the conterminous United States are 1%, 19%, and 80%. Using the STATSGO database (N. Bliss, query of NRCS STATSGO database, December 2005), the average soil carbon density for Histosols in the conterminous United States is 1,089 Mg C per ha, but this is an underestimate as many peatlands were not sampled to their maximum depth. Armentano and Menges (1986) reported average carbon density of conterminous United States' peatlands to 1-m depth of 1,147 to 1,125 Mg C per ha. Malterer (1996) gave soil carbon densities of conterminous United States' peatlands of 2,902 Mg C per ha for Fibrist, 1,874 Mg C per ha for Hemists, and 2,740 Mg C per ha for Saprists, but it is unclear how he derived these estimates. Batjes (1996) and Eswaran *et al.* (1995) gave average soil carbon densities to 1-m depth for global peatlands of 776 and 2,235 Mg C per ha, respectively. We chose to use an average carbon density of 1,500 Mg C per ha, which is in the middle of the reported range, for peatlands in the conterminous United States and Mexico.

F.2.3 Estuarine Soil Carbon Pools

Tidal wetland soil carbon density was based on a country-specific analysis of data reported in an extensive compilation by Chmura *et al.* (2003). There were more observations for the United States ($n = 75$) than Canada ($n = 34$) or Mexico ($n = 4$), and consequently there were more observations of marshes than mangroves. The Canadian salt marsh estimate was used for Alaskan salt marshes and mud flats. In the conterminous United States and Mexico, country-specific marsh or mangrove estimates were used for mudflats. Although Chmura *et al.* (2003) reported some significant correlations between soil carbon density and mean annual temperature, scatter plots suggest the relationships are weak or driven by a few sites. Thus, we did not separate the data by region or latitude and used mean values for scaling. Chmura *et al.* (2003) assumed a 50-cm-deep profile for the soil carbon pool, which may be an underestimate.

F.2.4 Plant Carbon Pools

While extensive data on plant biomass in individual wetlands have been published, no systematic inventory of wetland plant biomass has been undertaken in North America. Nationally, the forest carbon biomass pool (including above-ground and below-ground biomass) has been estimated to be 54.9 Mg C per ha (Birdsey, 1992), which we used for forested wetlands in the United States and Canada. This approach assumes that wetland forests do not have substantially different biomass carbon densities from upland forests. There is one

Table F.3 Plant carbon pools (Gt) and fluxes (Mt per year) of wetlands in North America and the world. Positive flux numbers indicate a net flux into the atmosphere, whereas negative numbers indicate a net flux into the ecosystem.

^a Biomass for non-forested peatlands from Vitt *et al.* (2000), assuming 50% of biomass is below-ground. Forest biomass density from Birdsey (1992) and forested area from Tarnocai *et al.* (2005) for Canada and from Hall *et al.* (1994) for Alaska.

^b Assumed 2000 g C per m² in above-ground and below-ground plant biomass (Gorham, 1991).

^c Biomass data from Mitsch and Gosselink (1993).

^d Biomass for non-forested wetlands from Gorham (1991). Forest biomass density from Birdsey (1992), and forested area from Hall *et al.* (1994) for Alaska and Dahl (2000) for the conterminous United States.

^e 50 g C per m² per yr sequestration from forest growth from a southeastern United States regional assessment of wetland forest growth (Brown *et al.*, 2001).

^f Assumed that global pools approximate those from North America because most salt marshes inventoried are in North America.

^g Twilley *et al.* (1992).

ND indicates that no data are available.

regional assessment of forested wetlands in the southeastern United States, which comprise approximately 35% of the total forested wetland area in the conterminous United States. We utilized the southeastern United States regional inventory to evaluate this assumption; above-ground tree biomass averaged 125.2 m³ per ha for softwood stands and 116.1 m³ per ha for hardwood stands. Using an average wood density and carbon content, the carbon density for these forests would be 33 Mg C per ha for softwood stands and

42 Mg C per ha for hardwood stands. However, these estimates do not include understory vegetation, below-ground biomass, or dead trees, which account for 49% of the total forest biomass (Birdsey, 1992). Using that factor to make an adjustment for total forest biomass, the range would be 49 to 66 Mg C per ha for the softwood and hardwood stands, respectively. Accordingly, the assumption of using 54.9 Mg C per ha seems reasonable for a national-level estimate.

The area of forested wetlands in Canada came from Tarnocai *et al.* (2005), for Alaska from Hall *et al.* (1994), and for the conterminous United States from Dahl (2000).

Since Tarnocai *et al.* (2005) divided Canadian peatland area into bog and fen, we used above-ground biomass for each community type from Vitt *et al.* (2000), and assumed that 50% of biomass is below-ground. We used the average bog and fen plant biomass from Vitt *et al.* (2000) for Alaskan peatlands. For other wetland areas, we used an average value of 20.0 Mg C per ha for non-forested wetland biomass carbon density (Gorham, 1991).

Tidal marsh root and shoot biomass data were estimated from a compilation in Table 8-7 in Mitsch and Gosselink (1993). There was no clear latitudinal or regional pattern in biomass, so we used mean values for each. Mangrove biomass has been shown to vary with latitude, so we used the empirical relationship from Twilley *et al.* (1992) for this relationship. We made a simple estimate using a single latitude that visually bisected the distribution of mangroves either in the United States (26.9°) or Mexico (23.5°). Total biomass was estimated using a root-to-shoot ratio of 0.82 and a carbon-mass-to-biomass ratio of 0.45, both from Twilley *et al.* (1992).

Plant biomass carbon data are presented in Table F.3.

F.3 CARBON FLUXES

F.3.1 Peatland Soil Carbon Accumulation Rates

Most studies report the long-term apparent rate of carbon accumulation (LORCA) in peatlands based upon basal peat dates, but this assumes a linear accumulation rate through time. However, due to the slow decay of the accumulated peat, the true rate of carbon accumulation will always be less than the LORCA (Clymo *et al.*, 1998), so most reported rates are inherently biased upwards. Tolonen and Turunen (1996) found that the true rate of peat accumulation was about 67% of the LORCA.

For estimates of soil carbon sequestration in conterminous United States' peatlands, we used the LORCA data from 82 sites and 215 cores throughout eastern North America (Webb and Webb III, 1988). They reported a median accumulation rate of 0.066 cm per year (mean = 0.092, sd = 0.085). We converted this value into a carbon accumulation rate of -0.71 Mg C per ha per year by assuming 58% C (see NRCS Soil Survey Laboratory Information Manual,

available on-line at <http://soils.usda.gov/survey/nscd/lim/>), a bulk density of 0.28 g per cm³, and an organic matter content of 69%. (Positive carbon fluxes indicate net fluxes to the atmosphere, whereas negative carbon fluxes indicate net fluxes into an ecosystem.) The bulk density and organic matter content were the area-weighted and depth-weighted average from all Histosol soil map units greater than 202.5 ha (n = 3,884) in the conterminous United States from the National Soil Information System (NASIS) data base provided by S. Campbell (USDA NRCS, Portland, Oreg.). For comparison, Armentano and Menges (1986) used soil carbon accumulation rates that ranged from -0.48 Mg C per ha per year in northern conterminous United States peatlands to -2.25 Mg C per ha per year in Florida peatlands.

Peatlands accumulate lesser amounts of soil carbon at higher latitudes, with especially low accumulation rates in permafrost peatlands (Ovenden, 1990; Robinson and Moore, 1999). The rates used in this report reflect this gradient, going from -0.13 to -0.19 to -0.71 Mg C per ha per year in permafrost peatlands, non-permafrost Canadian and Alaskan peatlands, and peatlands in the conterminous United States and Mexico, respectively (Table F.2).

F.3.2 Freshwater Mineral-Soil Wetland Carbon Accumulation Rates

Many studies have estimated sediment deposition rates in FWMS wetlands, with a geometric mean rate of 2.2 Mg sediment per ha per year (n = 26, arithmetic mean = 16.3, range 0 to 80.0) in a compilation by Johnston (1991), along with those reported more recently in Craft and Casey (2000). As can be seen by the difference between the geometric and arithmetic means, this dataset is log-normally distributed with several large outliers. Assuming 7.7% carbon for FWMS wetlands (Batjes, 1996), this gives a geometric mean accumulation rate of 0.17 Mg C per ha per year. Johnston (1991) and Craft and Casey (2000) reported more studies with only vertical

sediment accumulation rates, with a geometric mean of 0.23 cm per year ($n = 34$, arithmetic mean = 0.63 cm per year, range -0.6 to 2.6). If we assume a bulk density of 1.00 g per cm^3 for FWMS wetlands (Batjes, 1996; Smith *et al.*, 2001), this converts into an unrealistically large accumulation rate of 1.85 Mg C per ha per year.

We suggest that caution is necessary in interpretation of these data for a number of reasons. There is large variability in sedimentation rates among studies, and even within a site, sedimentation rates are highly variable depending on the local deposition environment (Johnston *et al.*, 2001). Researchers may have preferentially chosen wetlands with high sedimentation rates to study this process, providing a bias towards greater carbon sequestration. Rates of erosion and resultant deposition have substantially decreased during the last century in the conterminous United States (Craft and Casey, 2000; Trimble and Crosson, 2000). More fundamentally, it is important to distinguish between autochthonous carbon (derived from on-site plant production) and allochthonous carbon (imported from outside the wetland) in soil carbon storage. The soil carbon stored in peatlands is of autochthonous origin and represents sequestration of atmospheric carbon dioxide at the landscape scale. In contrast, a unknown portion of the soil carbon that is stored in FWMS wetlands is of allochthonous origin. However, conterminous United States' soils average between 0.9 and 1.3% soil carbon, which is much less than the average carbon content of FWMS wetlands (7.7%) (Batjes, 1996), suggesting a substantial autochthonous input to FWMS wetlands.

At a landscape scale, redistribution of sediments from uplands to wetlands represents net carbon sequestration only to the extent that the soil carbon is replaced in the terrestrial source area and/or decomposition rates are substantially lower in the receiving wetland (Stallard, 1998; Harden *et al.*, 1999). Agricultural lands are a major source of erosion (Meade *et al.*, 1990, as cited in Stallard, 1998), but it appears that, after large initial losses, soil carbon is relatively stable (Stallard, 1998; Smith *et al.*, 2001) or even increases (Harden *et al.*, 1999) under modern agricultural techniques. It is also generally assumed that sediment carbon deposited in anaerobic environments, such as occur in many wetlands, is relatively recalcitrant (Stallard, 1998; Smith *et al.*, 2001). For example, in a variety of Minnesota wetland soils, carbon

mineralization was approximately six times slower anaerobically than aerobically (Bridgman *et al.*, 1998). However, time since initial deposition and organic quality of sediments appears to be an important constraint on its relative reactivity. Kristensen *et al.* (1995) found that relatively fresh, labile organic matter had similar decomposition rates aerobically and anaerobically, whereas “aged,” recalcitrant organic matter decomposed ten times slower anaerobically. Gunnison *et al.* (1983) found that freshly flooded soils had twice as rapid carbon mineralization rates as sediments. In newly constructed reservoirs, sediments maintained these rapid mineralization rates even 6-10 years after initial flooding. Overall, these latter two studies suggest that there may be substantial carbon mineralization in freshly deposited allochthonous sediments in wetlands, but we feel that the data are not adequate to account for this effect quantitatively.

We use a landscape-level sediment sequestration rate of 0.17 Mg C per ha per year for FWMS wetlands in North America, while acknowledging the low level of confidence in this estimate. Johnston (1991) and Craft and Casey (2000) only gave sedimentation rates in FWMS wetlands in the conterminous United States. Since most FWMS wetlands in Canada are in more developed and agricultural regions, we felt that it was reasonable to use the sedimentation estimates from these studies. However, most Alaskan FWMS wetlands are relatively pristine, with little anthropogenic sediment input, but as described above, most have an extensive histic epipedon, so at least historically, they have actively accumulated soil carbon. Given that our soil carbon accumulation rate for Alaskan peatlands is 0.19 Mg C per ha per year, our sediment sequestration rate of 0.17 Mg C per ha per year for Alaskan FWMS wetlands does not seem unreasonable.

^a Used CH₄ flux of 2.5 g per m² per yr (range 0 to 130, likely mean 2 to 3) (Moore and Roulet, 1995) for Canadian peatlands and all Alaskan freshwater wetlands. Used CH₄ flux of 7.6 g per m² per yr for Canadian freshwater mineral-soil wetlands and all United States and Mexican freshwater wetlands and 1.3 g per m² per yr for estuarine wetlands—from synthesis of published CH₄ fluxes for the United States (see Table F.5).

^b Includes a 17-fold increase in CH₄ flux (Kelly *et al.*, 1997) in the 9000 km² of reservoirs that have been formed on peatlands (Rubec, 1996) and an estimated CH₄ flux of 15 g per m² per yr (Moore *et al.*, 1998) from 2,630 km² of melted permafrost peatlands (Vitt *et al.*, 1994).

^c Assumed trace gas fluxes from unvegetated estuarine wetlands (*i.e.*, mudflats) was the same as adjacent wetlands.

^d Bartlett and Harriss (1993).

^e Assumed that global rates approximate the North America rate because most salt marsh area is in North America.

^f Ehhalt *et al.* (2001), range of 92 to 237 Mt per yr.

^g Using rates from Bartlett and Harriss (1993) and historical loss of area in Table 1.

ND indicates that no data are available.

F.3.3 Estuarine Carbon Accumulation Rates

Carbon accumulation in tidal wetlands was assumed to be entirely in the soil pool. This should provide a reasonable estimate because marshes are primarily herbaceous, and mangrove biomass should be in steady state unless the site was converted to another use. An important difference between soil carbon sequestration in tidal and non-tidal systems is that tidal sequestration occurs primarily through burial driven by sea level rise. For this reason, carbon accumulation rates can be estimated well with data on changes in soil surface elevation and carbon density. Rates of soil carbon accumulation were calculated from Chmura *et al.* (2003) as described above for the soil carbon pool (rates in Mg C per ha per year are 3.3 for Mexican mangroves; 1.8 and 2.2 for mangroves and tidal marshes, respectively, in the conterminous United States; 2.1 for tidal marshes in Canada and Alaska). These estimates are based on a variety of methods, such as ^{210}Pb dating and soil elevation tables, which integrate vertical soil accumulation rates over periods of time ranging from 1–100 years. The soil carbon sequestered in estuarine wetland sediments is likely to be a mixture of both allochthonous and autochthonous sources. However, without better information, we assumed that *in situ* rates of soil carbon sequestration in estuarine wetlands is representative of the true landscape-level rate.

F.3.4 Extractive Uses of Peat

Use of peat for energy production is, and always has been, negligible in North America, as opposed to other parts of the world (WEC, 2001). However, Canada produces a greater volume of horticultural and agricultural peat than any other country in the world (WEC, 2001). Currently, 124 km² of Canadian peatlands have been under extraction now or in the past (Cleary *et al.*, 2005). A life-cycle analysis by these authors estimated that as of 1990 Canada emitted 0.2 Mt per year of CO₂-C equivalents through peat extraction. The United States' production of horticultural peat is about 19% of Canada's (Joosten and Clarke, 2002), which assuming a

similar life-cycle as for Canada, suggests that the United States produces 0.05 Mt of CO₂-C equivalents through peat extraction.

F.3.5 Methane Fluxes

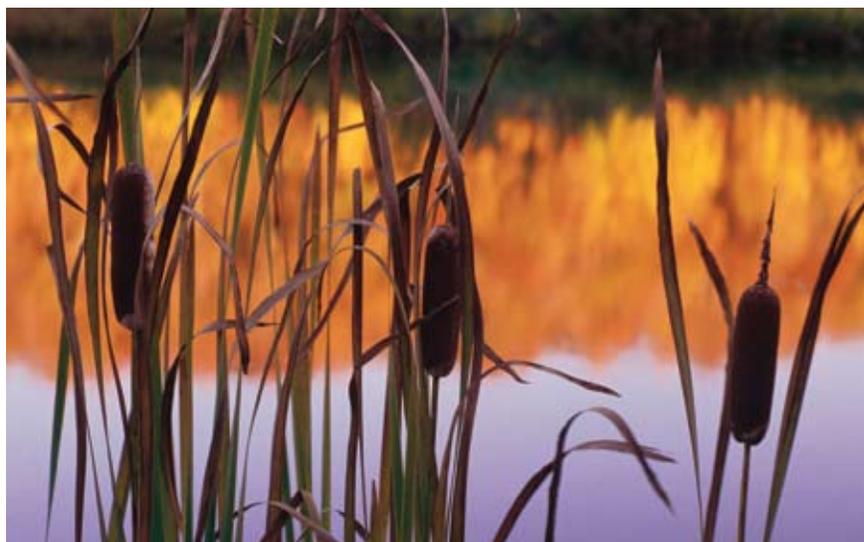

Moore and Roulet (1995) reported a range of methane fluxes from 0 to 130 g CH₄ per m² per year from 120 peatland sites in Canada, with the majority <10 g CH₄ per m² per year. They estimated a low average flux rate of 2 to 3 g CH₄ per m² per year, which equaled an emission of 2–3 Mt CH₄ per year from Canadian peatlands. We used an estimate of 2.5 g CH₄ per m² per year for Canadian peatlands and Alaskan freshwater wetlands (Table F.4).

To our knowledge, the last synthesis of field measurements of methane emissions from wetlands was done by Bartlett and Harriss (1993). We supplemented their analysis with all other published field studies (using chamber or eddy covariance techniques) we could find that reported annual or average daily methane fluxes in the conterminous United States (Table F.5). We excluded a few studies that used cores or estimated diffusive fluxes.

In cases where multiple years from the same site were presented, we took the average of those years. Similarly, when multiple sites of the same type were presented in the same paper, we took the average. Studies were separated into freshwater and estuarine systems.

In cases where papers presented both an annual flux and a mean daily flux, we calculated a conversion factor (annual flux/average daily flux) to quantify the relationship between those two numbers (Table F.5). When we looked at all studies (n = 30), this conversion factor was 0.36, suggesting that there is a 360-day emission season. There was surprisingly little variation in this ratio, and it was similar in freshwater (0.36) and estuarine (0.34) wetlands. In contrast, previous syntheses used a 150-day emission season for temperate wetlands (Matthews and Fung, 1987; Bartlett and Harriss, 1993). While substantial winter methane emissions have been found in some studies, it is likely that flux data from most studies have a non-normal distribution with occasional periods of high flux rates that are better captured with annual measurements.

Using the conversion factors for freshwater and estuarine wetlands, we estimated average annual fluxes from the average daily fluxes. The data were highly log-normally distributed, so we used geometric means. For freshwater wetlands, the geometric

mean estimated annual flux rate was 7.1 g CH₄ per m² per year (n = 74, 1 SE = 0.8, arithmetic mean = 38.6), which is very similar to the geometric mean measured rate of 8.1 g CH₄ per m² per year (n = 32, arithmetic mean = 32.1). For estuarine wetlands, the geometric mean estimated annual flux rate was 1.3 g CH₄ per m² per year (n = 25, 1 SE = 0.2, arithmetic mean = 9.8), which is smaller than the geometric mean measured rate of 5.0 g CH₄ per m² per year (n = 13, arithmetic mean = 16.9).

Finally, we combined both approaches. In cases where a paper presented an annual value, we used that number. In cases where only an average daily number was presented, we used that value corrected with the appropriate conversion factor. For conterminous United States wetlands, FWMS Canadian wetlands, and Mexican wetlands, we used a geometric mean flux of 7.6 g CH₄ per m² per year, and for estuarine wetlands, we used a geometric mean flux of 1.3 g CH₄ per m² per year.

F.3.6 Plant Carbon Fluxes

For ecosystems at approximately steady state, plant biomass should be reasonably constant on average because plant production is roughly balanced by mortality and subsequent decomposition. We assumed insignificant plant biomass accumulation in freshwater and estuarine marshes because they are dominated by herbaceous plants that do not accumulate carbon in wood. Sequestration in plants in relatively undisturbed forested wetlands in Alaska and many parts of Canada is probably small, although there may be substantial logging of Canadian forested wetlands for which we do not have data. Similarly, no data was available to evaluate the effect of harvesting of woody biomass in Mexican mangroves on carbon fluxes.

Tree biomass carbon sequestration averages -1.40 Mg C per ha per year in United States' forests across all forest types (Birdsey, 1992). Using the tree growth estimates from the southeastern United States regional assessment of wetland forests (Brown *et al.*, 2001) yields an even lower estimate of sequestration in above-ground tree biomass (approx. -0.50 Mg C per ha per year). We used this lower value and area estimates from Dahl (2000) to estimate that forested wetlands in the conterminous United States currently sequester -10.3 Mt C per year.

Table F.5 Methane fluxes measured in the conterminous United States. The conversion factor is the ratio of the daily average flux to the measured annual flux $\times 10^3$. The calculated annual flux was determined based upon the average conversion factor for freshwater (FW) and saltwater wetlands (SW). The measured annual flux was used if that was available; otherwise, the calculated annual flux was used.
